SUMMARY

A computer program for simulating a four-cylinder Stirling engine is presented. The thermodynamic model includes both continuity and energy equations and simplified, first-order momentum terms (flow resistance). Drive dynamics and vehicle load effects are included. The computer program includes a model of a hydrogen supply system to accelerate the engine.

The simulation can generate, at the user's option, steady-state or transient data. Steady-state power and torque predictions compare well with experimental data over a wide range of engine speeds and pressures. Simulated acceleration data compare well with results from a simplified four-cylinder model that was previously developed by the authors. Complete flow charts are provided.

INTRODUCTION

This report documents a computer program for simulating the steady-state and transient performance of a Stirling engine and serves as a users manual for the computer program. The evolution of the model is described below.

Stirling engine simulations have been developed for predicting steady-state engine performance. The simulations are based on the solution of the governing aerothermodynamic equations and are therefore quite complex. Pressure drops due to fluid flow resistance within the engine and to heat transfer coefficients between the heat exchangers and fluid and between fluid and the casing are calculated continuously during a cycle. Stirling engine performance is very sensitive to these factors.

Usual Stirling engine models include only two pistons and the working space between them. For analysis, the working space is usually segmented into control volumes corresponding to engine components - expansion space, heater, regenerator, cooler, and compression space. More than one control volume may be used to describe each component. Also, various heat transfer paths are included in the model. While many Stirling engines have more than one working space, the models used to predict performance generally do so for a single working space, and the resultant output power is multiplied by the number of working spaces. One such model has been developed by Tew, Jeffries, and Miao (ref. 1). It contains 13 control volumes in the working space. In that model, the energy equation is integrated within each control volume, while the pressure is assumed constant throughout the working space

over a cycle. Pressure drops throughout the engine are then back-calculated once the temperature distribution is known.

Although this approach is acceptable for performance calculations, it has shortcomings when the constant pressure assumption cannot be used, such as when the amount of hydrogen within a working space varies during a cycle. In a multicylinder engine, this can occur when transients are run from one operating point to another. Daniele and Lorenzo (ref. 2), as a first step in deriving a transient engine model, developed a model that can account for a change in the hydrogen-stored mass during a cycle. As in the Tew model, only one working space and two pistons are simulated. However, the number of control volumes in the working space is reduced to seven, one each for the expansion space, the heater, the cooler, and the compression space, and three for the regenerator. In that model, a thermal time constant associated with the regenerator mesh is included. Flow resistances and heat transfer coefficients are held constant over an engine cycle. Values of these parameters are specified as input data, using average values over a cycle, calculated from the output of Tew's model. Within each control volume, the continuity and energy equations are integrated and a simplified, first-order momentum term (flow resistance) is calculated. Upwind differencing (ref. 3) is used to calculate the interface volume temperatures for use in the energy equation. The resultant model has 17 state variables and uses a backward-difference integration scheme for problem solution. Results generated by that model compare well with experimental power and torque data over a wide range of speeds and pressures.

The aforementioned modeling approach (i.e., those in which only one working space is simulated) produces acceptable steady-state (power and torque) predictions when the working spaces in the engine are isolated. However, proposed controls schemes for four-cylinder Stirling engines require fluid transfer between working spaces. A more complete four-cylinder model is needed to analyze these control schemes.

One such four-cylinder model is also described in reference 2. In that model, each working space is further simplified to reduce computer run time. This simplification involves (1) reducing the number of control volumes in a working space from seven to three, (2) keeping the temperature within a control volume constant, and (3) assuming that the gas and regenerator mesh temperatures are equal. Steady-state results from this model are presented in references 2 and 4 and agree reasonably well with experimental data. The model was used to study various transient phenomena (ref. 4), and the associated computer program is documented in reference 5.

The simplified four-cylinder model is well suited for controls studies since it can produce transient results reasonably fast. Thus, many different cases can be run without using excessive computer time. However, the model lacks temperature variability, which may be important when simulating proposed control schemes, such as the injection of working fluid at one temperature into a control volume with resident working fluid at a different temperature.

To overcome this deficiency, the seven-volume, single-working-space model discussed earlier was extended to include all four pistons and working spaces; the resultant model is the subject of this report. A backward-difference integration scheme was used to account for the widely varying time constants associated with the flow and temperature dynamics. The integration scheme makes use of a multivariable Newton-Raphson iteration method (ref. 6) for convergence at a time point. To speed calculations, the Broyden update algorithm (ref. 7) was used to update the inverted Jacobian matrix during a transient.

This paper documents the seven-volume, four-working-space model and its computer implementation. A users manual and a test case are provided, along with complete flow charts. Results from the simulation are compared with results from the simplified four-cylinder model.

MODEL DESCRIPTION

The model consists of three parts: thermodynamic, drive geometry, and hydrogen supply. A schematic of the seven-volume, four-cylinder Stirling engine thermodynamic model is shown in figure 1. Each working space contains seven volumes - one each for the expansion space, the heater, the cooler, and the compression space, and three for the regenerator. A thermal time constant for the regenerator mesh is associated with each regenerator gas volume. Within each control volume, the continuity and energy equations are solved and a simplified first-order momentum term (flow resistance) is calculated. Upwind differencing is used to calculate interface volume temperatures (primed temperature variables in fig. 1) for use in the energy equation. All symbols shown in figure 1, as well as a complete symbols list, are given in appendix A. The equations used to model the engine are given in appendix B.

A schematic of the drive dynamics is shown in figure 2. Differential forces on the pistons are translated into torque through the vehicle drive geometry and summed to form total indicated torque. Torque due to engine friction is subtracted to form brake torque. This torque is available to drive auxiliaries and the vehicle load. The vehicle inertia and gear ratio are used in computing the effective load. The net torque is integrated once to give engine speed (PSIDT) and once again to give crank angle (PSI). The crank angle is used to generate piston position (using the crank geometry). The model can be run in this manner, or piston position can be forced as a function of time with torque and cycle performance calculated at constant speed.

A model of the working fluid supply system is shown in figure 3. This system is actually part of a mean pressure control system which modulates engine power by changing the amount of working fluid in the cycle. In order to accelerate the engine, working fluid is supplied to the engine. A slot in the piston rod is used to time the injection of working fluid into the various compression spaces in the engine. The timing is arranged to supply the fluid only when the pistons are near bottom (minimum) stroke. During this period, the pressure in the associated compression space is near a maximum, and the injected fluid functions to increase rather than decrease the engine torque. The check valves (fig. 3) remain open as long as the supply pressure (PSOURC) is greater than the corresponding compression space pressure. Also included in the supply model are rod leakage effects. These are indicated by WSSCN in figure 3 and allow study of the effects of mistimed flow injection into the system.

USERS MANUAL

Simulation Flow Diagram

The overall simulation structure is shown in figure 4. Run conditions are set in MAINST. Subroutine ICSTIR is then called to calculate initial conditions. PISTIN is called from ICSTIR to calculate the initial piston position. ICSTIR then calls INTEGR, which is the integration subroutine. INTEGR handles the incrementing of time, data output, and run termination. INTEGR calls the Stirling engine simulation subroutine STIRSM to obtain the information it needs for the Jacobian matrix that is required by the backward-difference integration. STIRSM calls TORLOS to calculate engine friction, auxiliary losses, and vehicle load effects; PISTIN, to calculate piston positions from crank angle and crank geometry; and HYSUPY, to calculate flow into the engine, the phasing of the injected flow, and rod leakage effects. STIRSM then returns to INTEGR.

In figure 4 the body of INTEGR is shown within a dashed line. The subroutines enclosed are actually subroutines to INTEGR. While they are called by and return to INTEGR, they are shown as calling one another to illustrate the looping that takes place within the subroutine. Once a Jacobian matrix is calculated, INTEGR calls DMINV for a matrix inversion, or BRYDON for updates to a previously generated matrix. Subroutine BRYDON contains the Broyden update algorithm. This algorithm permits the simulation operating point to be changed without having to calculate a new Jacobian matrix. The algorithm does this by continually updating the known inverted Jacobian matrix. This can significantly reduce the computation time, since generating Jacobian matrices and inverting the matrices can be very time consuming. The use of the algorithm will be discussed in more detail later.

Convergence is then checked. If the simulation is not converged, more passes are made through INTEGR to generate better iteration guesses or, if necessary, a new Jacobian matrix. If converged, INTEGR calls TRAP to do a trapezoidal integration on the product of the pressure and volume in both the expansion and compression spaces. TRAP returns to INTEGR, which then calls OUTSTR if a printout is desired at the current time. OUTSTR returns to INTEGR; then GUESSE is called to predict the next set of state variables for the next time step. This is done until the desired maximum number of time steps have been run, at which time INTEGR terminates the run. Flow charts for all subroutines are given in appendix C.

Program Setup

The program setup is done in the main program MAINST. Switches are set to indicate the type of transient desired. Engine geometry and flow data are input data. Tables I to XIII indicate the required input as well as the options available. In table I, baseline engine geometry data are listed. The total regenerator volume (VR) excludes the volume of the mesh. Tables II to IV list the required heater, cooler, and regenerator data, respectively. The initial guesses for the temperature distribution within a working space are shown in table V. All four working spaces start out with this distribution as a first guess. All of the simulation constants are listed

in table VI. Flow resistances between the volumes are shown in table VII. Hydrogen constants are listed in table VIII. Data for the implicit integration method are listed in table IX. In most cases, the indicated integration settings should lead to convergence. However, experience has shown that increasing MPAS and/or TOLPCG can be helpful for difficult convergence problems.

Another method of overcoming convergence problems is to increase TOLSS. This is done internally in the program if the number of iterations using one matrix exceeds 20 passes, or if a new matrix needs to be generated. Once the program converges, TOLSS is set back to .0001 for the next time point. If MPAS is exceeded, the simulation will continue to run, but will produce a debug output at that time point indicating that MPAS has been exceeded.

The different switch options available can be selected by a set of switches defined in table X. Table XI lists all the run conditions that must be specified, while table XII defines the load characteristics. The cycle data are defined in table XIII. Note that if a supply transient is not desired, NCYSUP and NCYSTP from table XI must be set greater than NUMBCY.

Output Options

The user may select from a number of output options and a debug option. If ICALC = 1, a short printout is specified. The short printout header is shown in table XIV. Output variables include the heater temperature (TWH), cooler temperature (TWC), cycle mean pressure (CYCLPR), engine drive mode (NONENG), number of cycles to be run (NUMBCY), piston rod leakage area (ALEAK), supply pressure (PSOURC), hydrogen supply temperature (TSOURC), the time point to start the hydrogen supply (ISUPST), and the time point to end the hydrogen supply (ISPSTP).

Results are also printed at specified time steps. Power, torque, crank angle, mean pressure, and engine speed are printed. ITRAN indicates the number of time steps taken up to and including the printout; KWORK is a counter indicating the number of time steps in the calculation of the pressure-volume area (note that if KWORK = 201, 200 time steps were taken, since the first time step printed out is the initial condition).

If ICALC = 0, a long printout is specified; the long printout header is shown in table XV. At each specified time step a complete listing of all engine variables is generated. Note that the output is arranged in rows of four (except for the overall engine parameters). The first row corresponds to the first working space, the second corresponds to the second, etc. The output variables include all pressures, temperatures, and stored masses for each working space, as well as the power, torque, and supply flow. The last row of the long printout contains the same overall engine parameters as the short printout.

The user may select a debug option to aid in solving problems that may occur in the simulation. This option is specified in MAINST by NOBUG. If NOBUG = 1, the debug option will not be activated unless (a) there is a problem with convergence (the maximum number of iteration passes is exceeded without convergence), or (b) there is a problem in generating a partial derivative for the Jacobian matrix. The debug printout comes from STIRSM. The debug option is selected by the user by setting NOBUG = 0. A sample of the debug printout is shown in table XVI. This option is further described in appendix C.

OUTPUT - TEST CASE

Supply Transient

A supply transient is provided as an output test case. The assumed initial conditions for the transient are a mean pressure of 5 MPa and a speed of 2000 rpm. After 10 cycles, hydrogen is injected to accelerate the engine. The hydrogen supply pressure is 10 MPa and the supply temperature is 283 K. Piston rod leakage is assumed to be zero for this test case. The corresponding Fortran input for MAINST is shown in table XVII. The transient is defined by CYCLPR = 5, SPDRPM = 2000, NCYSUP = 10, NUMBCY = 100, PSOURC = 10, TSOURC = 10, and ALEAK = 0. The Broyden update algorithm is used (IBRYTH = 1), the step size is determined by the specified 200 points per cycle (NPTPCY = 200), and a short printout is desired every 200 points (ICALC = 1 and IPRTOP = 200).

The printout for this test case is given in table XVIII. Note that time is incremented so that the specified number of integration points per cycle is obtained. Therefore, the time step is a function of engine speed. Sixty-one engine cycles (12 201 time steps at 200 per cycle) were simulated before the specified limit on CPU time was exceeded. On the IBM 3033, the simulation ran for 60 min of CPU time, taking about 1 min of CPU time per engine cycle.

Figure 5 shows a comparison of acceleration results from this simulation (dashed lines) with results from the simplified model (solid lines). Data for power, torque, and mean pressure are plotted against time from the start of the hydrogen supply (both simulations were run for 10 cycles before supply input). At a 5 MPa mean pressure, the seven-volume model predicts more power (and thus more torque) than the simplified model (as seen by the steady-state maps of ref. 2). Thus, with the same load, losses, and gear ratios used on both simulations, the seven-volume model reaches steady-state at a higher speed than the simplified model.

At time equal zero in figure 5, the seven-volume model is running at 2400 rpm, while the simplified model is running at 2000 rpm. A hydrogen supply transient is then simulated in both cases, assuming a 10-MPa supply bottle. Pressure rises at about the same rate in both simulations. Power rises in both simulations at about the same rate, with the difference remaining fairly constant. Total torque also rises in both simulations. However, the difference between the total torques decreases slightly because of the difference in speed-torque maps as determined by each of the models. Both simulations give basically the same dynamic response; however, the three-volume model uses much less CPU time (about 1 sec of CPU time per cycle) because of its fewer state variables (14 versus 70).

Thus, both simulations are useful for controls analysis. The three-volume simulation (ref. 5) can be used for evaluating many control strategies or doing parametric studies, while the seven-volume simulation can be used to study detailed performance during specific controls transients.

Cycle Analysis

The simulation can be used to look at individual cycles. Results from a steady-state case (no supply) are shown in figure 6. Piston position, individual torques, total torque, compression space pressures, and compression space temperatures are shown. Speed is constant at 2000 rpm for this case. Results are similar to those presented for the simplified model in reference 4, except for the overall torque and compression space temperatures. Overall torque (fig. 6(c)), shows a low frequency oscillation at steady state which was not observed with the simplified (ref. 5) model. Further investigation, however, showed that the simulation had not quite reached steady state. Data are presented after eight engine cycles. The oscillations are approximately 1 N-m in 61 N-m, or about 1.6 percent. The reason for the torque oscillation is that the pressures within the working spaces are not at steady state, due to the slow response of the regenerator metal lumps (not included in the three-volume model).

Figure 7 shows the supply transient response of the engine with no piston rod leakage. The piston motion, individual torques, total torque, compression space pressures, compression space temperatures, supply flow, and rod leakage flow are plotted for three cycles. Again, results are similar to those presented for the simplified model in reference 4. Note, however, that compression space temperatures (fig. 7(e)) do drop because of the injection of cold working fluid and that compression space pressures (fig. 7(d)) rise because of the increase in stored mass. No torque droop is indicated in figure 7(c).

The same supply transient was run with a rod leakage area of 3.2 cm^2 (0.5 in^2); results are shown in figure 8. No torque droop is indicated in figure 8(c), even though there is a mistiming of the injected flow. Compression space temperatures, however, do fall more rapidly than in the non-leakage case.

CONCLUSIONS

A detailed seven-volume, four-working-space Stirling engine computer simulation has been developed. The simulation model includes drive dynamics and vehicle load effects. The simulation program includes subroutines which allow for simulation of control strategies, such as acceleration of the engine by adding hydrogen to the system.

All input data required to run the program are described. Flow charts of the overall simulation and the subroutines are also given. The simulation is modular to allow for easy modification of the model.

An input routine is provided in which the user specifies the transient to be run and supplies the necessary engine geometry data. The type of output is also selected by the user. Very detailed printouts at prescribed intervals can be selected; alternatively, less detailed printouts can be selected. The integration step size and the printout interval do not have to be the same.

Simulation test cases have been run, and results have been compared with results obtained from a simplified three-volume simulation. The simulations produce similar results, with the more detailed simulation (with

temperature dynamics) exhibiting more engine output power than the simplified simulation at the same engine speed and pressure. The detailed simulation shows variations in compression space temperature due to injected mass; the simplified simulation has no temperature variation.

The detailed simulation can be used to predict steady-state or transient performance of the engine. Engine accelerations can be run with or without piston rod leakage. The acceleration data presented herein can be used to verify the transient operation of the simulation program when actual engine data become available.

APPENDIX B

MODEL EQUATIONS

The equations used to model the fluid dynamics and thermodynamics are ordinary differential equation approximations of the complex partial derivative flow equations. Mass flow is assumed to occur due to pressure differential between the gas nodes. In figure 1 the pistons are numbered in the order in which they reach top stroke, as is indicated by the arrows in the piston heads. A double subscript notation has been adopted in which the first subscript denotes a volume position within a working space, and the second subscript denotes the working space.

Representative equations are

$$\dot{w}_{i,j} = \frac{(P_{i,j} - P_{i+1,j})}{S_{i,j \rightarrow i+1,j}} \quad \begin{matrix} j = 1, 2 \dots 4 \\ i = 1, 2 \dots 6 \end{matrix}$$

where the arrow indicates flow resistance measured between the volumes.

$$\dot{w}_{s_{i+1,j}} = \dot{w}_{i,j} - \dot{w}_{i+1,j} \quad \begin{matrix} j = 1, 2 \dots 4 \\ i = 0, 1 \dots 6 \end{matrix}$$

$$\dot{w}_{0,j} = \dot{w}_{7,j} = 0.0$$

and

$$P_{i,j} = \frac{w_{s_{i,j}}^R T_{i,j}}{V_{i,j}} \quad \begin{matrix} j = 1, 2 \dots 4 \\ i = 1, 2 \dots 7 \end{matrix}$$

Volumes are assumed to vary with piston position. For volume 1 in working space 1

$$V_{1,1} = V_{1,1_0} + \left(\frac{l}{2} - x_1\right) A_p$$

Piston position is a function of crank angle:

$$x_i = \frac{L}{2} \cos \psi_i + \sqrt{R_L^2 - \frac{L^2}{2} \sin^2 \psi_i} - \sqrt{R_L^2 - \frac{L^2}{2}} \quad i = 1, 2, \dots$$

The energy equation used to calculate the change in temperature in a volume is complicated by the oscillatory nature of the Stirling cycle. The form of the equation is

$$\dot{w}_{s,i,j} T'_{i,j} = \dot{w}_{i-1,j} (\gamma T'_{i-1,j} - T_{i,j}) - \dot{w}_{i,j} (\gamma T'_{i,j} - T_{i,j}) + \frac{Q_{i,j}}{c_v} + \frac{\text{Work}_{i,j}}{J_c}$$

where

$$j = 1, 2, \dots, 4$$

$$i = 1, 2, \dots, 7$$

$$\dot{w}_0 = \dot{w}_7 = 0$$

and where the heat flows into and out of the gas are modeled as

$$\dot{Q} = hA(\Delta T)$$

Primed temperature variables denote interface volume temperatures and are determined by upwind differencing (ref. 1). The method assumes that the gas temperature has the same temperature profile as the regenerator matrix temperature. Representative equations for positive and negative flows are

$$\left. \begin{aligned} \dot{w}_{i,j} \geq 0, T'_{i,j} &= T_{i,j} - \frac{(T_{m3,j} - T_{m5,j})}{4.0} + \frac{\dot{w}_i \Delta t (T_{m3,j} - T_{m5,j})}{4.0 \dot{w}_{s,i,j}} \\ \dot{w}_{i,j} < 0, T'_{i,j} &= T_{i+1,j} - \frac{(T_{m3,j} - T_{m5,j})}{4.0} + \frac{\dot{w}_i \Delta t (T_{m3,j} - T_{m5,j})}{4.0 \dot{w}_{s,i+1,j}} \end{aligned} \right\} \begin{aligned} j &= 1, 2, \dots, 4 \\ 2 \leq i &\leq 5 \end{aligned}$$

$$\left. \begin{aligned} \dot{w}_{i,j} \geq 0, T'_{i,j} &= T_{i,j} \\ \dot{w}_{i,j} < 0, T'_{i,j} &= T_{i+1,j} \end{aligned} \right\} \quad i = 1, 6$$

The regenerators are modeled as thermal lags:

$$T_{m,i,j} = \frac{h_i A_i}{c_{p_m} \dot{w}_{s_m}} (T_{i,j} - T_{m,i,j}) \quad \begin{aligned} j &= 1, 2, \dots, 4 \\ i &= 3, 4, 5 \end{aligned}$$

Torque is calculated as a function of differential forces on the pistons, which are summed through the drive geometry. A representative equation is

$$T_1 = \frac{L}{2} [P_{1,1}A_p - P_{7,2}(A_p - A_n)\sin \psi_1] \left(\frac{1 + \frac{L}{2} \cos_1 \psi_1}{\sqrt{R_L^2 - \frac{L}{2} \sin^2 \psi_1}} \right)$$

Also included in the model are simplified vehicle load effects and engine power losses due to mechanical friction and auxiliaries. Figure 2 shows a schematic of how these losses are calculated. Torques from the pistons are summed to form indicated torque. Torque due to mechanical friction (TFRICT) is subtracted to form brake torque. The resultant torque is available for engine auxiliaries (TAUX) and also for vehicle load effects, such as rolling resistance (TRRF) and drag (TDRAG).

APPENDIX C

FLOW CHARTS

This appendix contains flow charts for the main program and all the sub-routines of the simulation. Most flow charts are straightforward, with the possible exception of that for subroutine INTEGR. INTEGR performs both the incrementing of time and the integration of the state equations. The integration scheme is implicit. It is a backward-difference integration which uses a multivariable Newton-Raphson iteration for convergence at a time point. This type of integration is stable for both large and small step sizes. This stability is important when there is a large spread in eigenvalues for the system, which is the case when both pressure-flow and temperature dynamics are simulated. The implicit integration scheme can handle the widespread dynamics while insuring stability. To help one understand how subroutine INTEGR works, the following description is provided. To help one follow the INTEGR flow chart, statement numbers corresponding to the Fortran listing are given in the flow chart.

Integration Scheme

The integration scheme is a backward difference method which uses a multivariable Newton-Raphson iteration scheme for convergence. Guess variables are updated by using the old guess vector \overline{VS}_{old} , the current error vector \overline{E} , and an inverted Jacobian matrix \overline{EMAT} :

$$\overline{VS}_{new} = - \overline{EMAT}^{-1} \times \overline{E} + \overline{VS}_{old} \quad (C1)$$

\overline{EMAT} is a Jacobian matrix of partial derivatives (i.e., changes in error variables with respect to changes in state variables):

$$EMAT(I,J) = [E(J) - ERRBSE(J)]/DELTAV(I) \quad (C2)$$

Updating takes place when the errors are converged within tolerance. With this technique, both steady-state and transient solutions can be obtained by redefining the error variables. In steady state all states are at rest; thus

$$\overline{VDOT} = 0.0 = \overline{E} \quad (C3)$$

For a transient case

$$\overline{V} \text{DOT} \times \text{DEL T} - (\overline{V}_{\text{new}} - \overline{V}_{\text{old}}) = \overline{E} \quad (\text{C4})$$

Equations (C3) and (C4) are converged when all the elements of \overline{E} are with a specified tolerance. It should be noted that all the equations are scaled by the converged state to help convergence.

In order to use this method, a Jacobian matrix must be calculated (usually by finite differences) and then inverted. This can be very time consuming. Therefore, the logic in INTEGR allows for calculation of a new matrix only under adverse conditions. Examples might be (1) too low a convergence rate of the simulation ($\text{PCNCHG} < \text{TOLPCG}$), or (2) the number of allowable passes (MPAS) being exceeded. Also to speed convergence, the error tolerance (for eq. (C4)) is increased if more than one matrix must be calculated at the same time or if more than 20 passes are required using the same matrix. Once convergence is obtained, the tolerance is reset to its nominal value.

Perturbation Calculation

Several features in INTEGR help the implicit integration scheme converge. Of primary importance is the generation of a "good" Jacobian matrix. All the partial derivatives must be representative of the linear behavior of the system at a given operating point. Since finite differences are used, the sizes of the perturbations of the states are important: If the perturbations are too large, errors will be introduced by the system nonlinearities; if they are too small, the partial derivatives will be in error due to numerical problems (without double precision arithmetic).

Thus, a tuning mechanism has been introduced into INTEGR to optimize the sizes of the perturbation. First the sum of squares of all the changes in the errors is calculated for each perturbation. Once this is done, the "goodness" of the partial is checked by calculating

$$\text{XXX} = \frac{1}{N} \sqrt{\sum_{i=1}^N [E(I) - \text{ERRBSE}(I)]^2} \quad (\text{C5})$$

for each state variable and then checking if

$$\text{TOL1} \leq \text{XXX} \leq \text{TOL2} \quad (\text{C6})$$

If all XXX's fall within the tolerance band, the matrix is considered good. For this simulation, $\text{TOL1} = 0.001$ and $\text{TOL2} = 0.01$. Since all the errors are scaled, this tolerance band lies between 0.1 and 1 percent. For a more linear system, the band could be larger; for a more nonlinear system, smaller.

Scaling of Perturbations

In general, for the initial perturbations at a point, the XXX's will not fall in the tolerance band described above. Thus, INTEGR scales the perturbations to try to force the XXX's within the band. This is done by calculating

$$YYY = REF/XXX \quad (C7)$$

for each state variable. REF is defined as being the center of the tolerance band:

$$REF = \frac{(TOL1 + TOL2)}{2.0} \quad (C8)$$

Once a set of YYY's has been calculated such that the XXX's fall within the band, the set of YYY's is stored. After this has been done for all N states, the scaling vector YYY is generated. When a new matrix is needed, the scaling vector YYY is applied to the current states to determine first guesses for the perturbations needed to obtain new partial derivatives. If for any state variable the new XXX falls outside the tolerance band, YYY is updated and the new result stored. This method generally reduces the number of passes required for subsequent matrix generation.

Error Messages

In generating a partial derivative, a situation may arise where XXX never gets within tolerance. When this happens, the program prints an error message: "CHECK INPUT - BAD PARTIAL DERIVATIVE", prints a debug output to help the user diagnose the problem, and then stops the simulation. This is the only time when the simulation is stopped, except for the normal exit (i.e., ITRAN incremented to its maximum value, ITRMAX). In general, nonconvergence will occur when inconsistent coding is added to the simulation. One example would be if a piston ring leakage flow was calculated and subtracted from one working space but not added to the adjacent working space.

Another error message occurs when the simulation does not converge. This situation occurs when MPAS (set at 50) is exceeded. A message is printed; for example, "ITERATION FAILURE 69 51 32 15". The numbers printed out are the number of converged errors (may be any number from 0 to N-1; 69 is shown here), the number of iteration passes (MPAS + 1), the number of times the BROYDEN update algorithm has been called for the current matrix (32 here), and the point at which the convergence failed (ITRAN). In this situation, a debug output is printed from STIRSM which indicates

| | |
|-------|--|
| I | counter for the system order |
| VS | current guess variables |
| VCONV | past converged guess variables |
| VWS | state variables |
| VDOT | current state derivative |
| VDOTT | converged state derivative between current time point and past converged value |
| E | current errors |

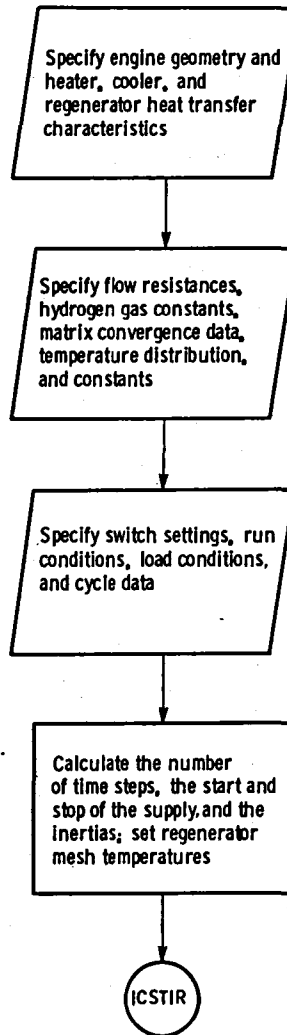

After the printout, the simulation continues. Note that with this method a convergence failure may occur, but the errors will be very close to the tolerance band. After the failure, the simulation may recover. For this reason the simulation is allowed to continue and the user may make a judgment as to the validity of the data after a convergence failure.

The occurrence of many convergence failures in a transient, however, usually indicates a need for the user to increase tolerance or check his input and coding.

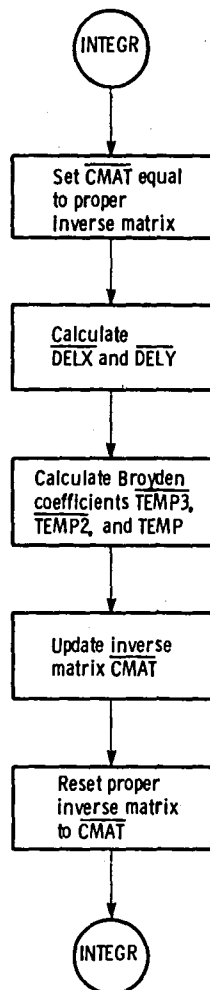

Broyden Update Algorithm

As stated earlier, it is time consuming to calculate a Jacobian matrix, and even more time consuming to invert a matrix for a large system. Usually double precision is required (as in DMINV). Lack of speed of the matrix inversion algorithm can be prohibitive, especially in a controls model where long transients are needed to evaluate controls schemes. One possible means of avoiding this problem is to generate the inverse, and then to continually update it with information gained as the inverse is used. One way to do this is by using the Broyden update algorithm, found in subroutine BRYDON. The use of the algorithm is controlled by IBRYTH, which is set in MAINST.

```

The flowchart illustrates the iterative Gauss-Seidel method for solving a system of linear equations. It begins with an initialization step (L1) where the inverse of the Jacobian matrix is taken and the MATRIX is reset to 0. This step is influenced by inputs B and C. The process then enters a loop starting with calculating the update vector \overline{VMAT} to the guess vector \overline{VS} (L2). A convergence check (G1) follows, calculating the largest percent change (BIGNUM) in state variables. If the change is significant, the RATIO is set to the minimum of RAT or BIGNUM, and \overline{VMAT} is scaled by RATIO/BIGNUM (L4, L5). The guess vector \overline{VS} is then updated (L6). The iteration counter NITER is incremented, and the sum of squares of errors (SESP) is calculated (L7). The process then loops back to the update vector calculation (L2) if the convergence criteria are not met. The final output is the updated guess vector \overline{VS} and the calculated SESP, which are then used to update the inputs B, C, N, M, and G.

|--------|---------|--|
| ISS | 0 | Set up initial conditions |
| | 1 | Run transient (set internally in program) |
| ICALC | 0 | Detailed printout |
| | 1 | Shortened printout |
| MATRIX | 1 | If initial guesses do not converge the simulation, generates a Jacobian matrix |
| NONENG | 0 | Force crank angel as a function of time |
| | 1 | Run the simulation as an engine |
| IPRTOP | NN | Printout data every NN points |
| IBRYTH | 0 | Do not use BROYDEN update algorithm |
| | 1 | Use BROYDEN update algorithm |
| IHPCNV | 0 | Use logic in program to determine need for a new Jacobian matrix |
| | 1 | Generate a new Jacobian at every time point |
| NOBUG | 0 | No debut output |
| | 1 | Internally set to give a debug output when a convergence failure or matrix generation problem occurs |

TABLE XI. - PROGRAM INPUT: RUN CONDITIONS

| Name | Setting | Function |
|---------|---------|------------------------------------|
| ALEAK | 0 | Piston rod leakage area |
| PSOURC | 15.0 | Hydrogen bottle source pressure |
| TSOURC | 10.0 | Hydrogen bottle source temperature |
| SPDRPM | 2000 | Desired engine speed |
| CYCLPR | 5.0 | Initial engine pressure |
| SPDMAX | 4000 | Maximum engine speed |
| CYCLPM | 15.0 | Maximum engine pressure |
| NCYSUP* | 10 | Start hydrogen supply |
| NCYSTP* | 200 | End hydrogen supply |

*If no supply transient is desired, make NCYSUP and NCYSTP greater than NUMBCY.

TABLE XII. - PROGRAM INPUT: LOAD CONDITIONS

| Name | Setting | Function |
|---------|----------|-------------------------|
| GTRAN | 1.0/2.53 | Transmission gear ratio |
| GR | 1.5 | Gear ratio |
| WTENG | 0 kg | Engine mass |
| WTWHEEL | 29.48 kg | Mass of a wheel |
| WTCAR | 1420 kg | Mass of a car |
| RWHEEL | 30.48 cm | Tire wheel radius |

TABLE XIII. - PROGRAM INPUT: CYCLE DATA

| Name | Setting | Function |
|--------|---------|------------------------------------|
| NPTPCY | 200 | Number of integration points/cycle |
| NUMBCY | 3 | Number of desired cycles |

| 16. Abstract A computer program for simulating the steady-state and transient performance of a four-cylinder Stirling engine is presented. The thermodynamic model includes both continuity and energy equations and linear momentum terms (flow resistance). Each working space between the pistons is broken up into seven control volumes. Drive dynamics and vehicle load effects are included. The model contains 70 state variables. Also included in the model are piston-rod-seal leakage effects. The computer program includes a model of a hydrogen supply system, from which hydrogen may be added to the system to accelerate the engine. Flow charts are provided. | | | | | |
